Tropical Affine Rigidity: Vanishing Discrepancy iff Single-Atom Fourier Concentration

- **Verdict:** INCONCLUSIVE
- **Bridge:** Tropical Fourier Analysis (Tropical Geometry / Idempotent (Maslov) Harmonic Analysis) $\times$ Affine-Function Recognition Decision Problem (membership in the AC^0 -decidable class of degree-1 tropical polynomials, equivalently the zero-discrepancy promise problem)
- **Recorded:** 2026-04-27 00:22 UTC
- **Entry ID:** 81928f9c440e

Statement

Let f be a TropicalPolynomial over a finite domain $D = \{-N, \dots, N\} \subset \mathbb{Z}$ (min-plus semiring). Let $F = \text{FourierTransform}(f)$ denote its TropicalFourierTransform (Legendre-Fenchel transform: $F(y) = \min_{\{x \in D\}} \{f(x) - xy\}$ over a finite slope grid Y), and let $m(f) = \text{MinimalFourierCoefficient}(f) = \min_{\{y \in Y\}} F(y)$. Then $\text{DiscrepancyCalculation}(f) = 0$ if and only if f is tropically affine, i.e., there exist a in Y and b in R with $f(x) = ax + b$ for all x in D ; moreover, in this affine case the support $\{y : F(y) = m(f)\}$ is the singleton $\{a\}$ and $m(f) = -b$. Equivalently, $\text{DiscrepancyMeasure}(f) > 0$ iff the level set $\text{argmin}_y F(y)$ has cardinality unequal to 1 in the regular position OR F attains its minimum $-b$ at exactly the unique slope a only when f is affine — formally: $\text{Discrepancy}(f) = 0 \Leftrightarrow |\{y \in Y : F(y) = m(f)\}| = 1 \wedge f(x) \equiv (\text{argmin}_y F(y)) * x - m(f)$.

Rationale

This sub-conjecture sharpens axiom A3 ($\text{DiscrepancyMeasure}$ bounded by $\max |\text{Fourier coefficient}|$) at its extremal saturation point. A3 says discrepancy is controlled from above by Fourier magnitudes; the natural converse extremal case is when discrepancy collapses to zero: this should force the Legendre-Fenchel transform to be a singular Dirac-like object on the slope grid, since affine functions are the unique ‘tropically uniform’ (curvature-free) elements. The conjecture additionally invokes A2 (invertibility of TropicalFourierTransform on a privileged subclass): affine polynomials are precisely the fixed atoms of the involution from the existing Legendre-Fenchel sub-conjecture, so the singleton-support claim gives a constructive certificate that those polynomials sit at the boundary of the invertibility class. If true, this yields a linear-time complexity-theoretic decision procedure for affineness via discrepancy evaluation.

RESULT: INCONCLUSIVE not enough seeds supported
```

Judge reasoning

The test's own RESULT line explicitly states 'INCONCLUSIVE not enough seeds supported', and the suspiciously constant 0.6667 metric across all seeds suggests a tautological aggregate check rather than genuine verification of the biconditional's adversarial failure modes. | next: Rewrite the test to explicitly construct piecewise-linear f with multiple slopes tying for $\arg\min F(y)$, verify singleton-support on affine instances, and report per-seed Pearson correlation on perturbed-affine stress tes

Continued Fraction Depth of Spectral Ratio Bounds Discrepancy

- **Verdict:** INCONCLUSIVE
- **Bridge:** Diophantine approximation (continued-fraction expansions and partial-quotient growth, in the spirit of Khinchin and Gauss-Kuzmin metric theory) $\times$ Discrepancy-based randomized two-party communication complexity lower bounds for ± 1 sign matrices
- **Recorded:** 2026-04-27 00:31 UTC
- **Entry ID:** 71ce01b16c1e

Statement

Let $M \in \{-1, +1\}^{N \times N}$ with $N=2^n$ have singular values $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_N$, and let $\rho(M)=\sigma_2/\sigma_1 \in [0,1]$. Let $(a_1, a_2, \dots, a_K)$ be the simple continued-fraction expansion of $\rho(M)$ truncated at $K=\lceil \log_2 N \rceil$ partial quotients (computed via the Euclidean algorithm on a $4N$ -digit decimal truncation of ρ), and define $S(M)=\sum_{i=1}^K \log(1+a_i)$. Then for every $n \geq 3$ and every ± 1 sign matrix M of size $2^{n \times 2}n$, $\text{disc}(M) \cdot N \geq c \cdot \sigma_1(M) / (1 + S(M))$ for an absolute constant $c=0.05$, where $\text{disc}(M)$ is the combinatorial rectangle discrepancy of M .

Rationale

Highly structured matrices (Hadamard, Sylvester, AND/XOR-lifted indicators) have spectra that are integer or low-height rational, forcing σ_2/σ_1 to be exactly 0, 1, or a fraction with tiny partial quotients — yielding small $S(M)$ and hence the well-known large $\text{disc} \cdot N \approx \sigma_1$. Generic matrices satisfy Gauss-Kuzmin statistics with partial quotients distributed like $1/(k(k+1))$ and $S(M)=\Theta(\log N)$, exactly compensating their $\sigma_1=\Theta(\sqrt{N})$ into $\text{disc} \cdot N=\Theta(\sqrt{N})$. The Diophantine-approximation lens has, to my knowledge, never been applied to the spectral side of the discrepancy method, even though Khinchin-style metric theory is the natural quantitative refinement of 'how rational is the spectral ratio'.

```

TypeError: run_trial.<locals>.<lambda>() missing 1 required positional argument: '_'

Judge reasoning

The test crashed with a `TypeError` (`lambda` missing positional argument `'_'`) before any trials produced data, so neither the support nor falsification criteria can be evaluated. | next: Fix the `M_type` `lambda` signature in `run_trial` so all four ensembles can be instantiated uniformly, then rerun the 140-triple sweep.

Young-Flattening Rank Gap Lower-Bounds Padded-Permanent Border Rank

- **Verdict:** INCONCLUSIVE
- **Bridge:** Geometric Complexity Theory via Young flattenings (Landsberg-Ottaviani equivariant rank obstructions) $\times$ Border rank of the padded $m \times m$ permanent tensor Per_m viewed as a slice of det_n
- **Recorded:** 2026-04-27 01:05 UTC
- **Entry ID:** 0e80f2d2c50a

Statement

Let Per_m be the $m \times m$ permanent and det_n its $n \times n$ padded determinant embedding ($n \geq m^2$). Let $\text{YF}_k(T)$ denote the rank of the Young flattening of tensor T indexed by the partition $(k, 1^{\{m-k\}})$ acting on the symmetric m -th power of $C^{\{m,2\}}$. Conjecture: for all $2 \leq m \leq 6$ and all $1 \leq k \leq m-1$, the equivariant rank gap $\delta(m,k) := \text{YF}_k(\text{det}_n \text{ viewed as } \text{Per}_m\text{-padding}) - \text{YF}_k(\text{Per}_m)$ satisfies $\delta(m,k) \geq c \cdot \binom{m}{k} \cdot (n - m^2 + 1)$ with absolute constant $c = 1/2$, and consequently the border rank lower bound $\text{brk}(\text{Per}_m) \geq \max_k \text{YF}_k(\text{Per}_m) / \binom{m-1}{k-1}$ is tight to within a factor of m .

Rationale

Young flattenings are the only currently known equivariant obstructions that have produced super-additive border-rank lower bounds for permanents (Landsberg-Michalek), yet no quantitative law

connects their rank gaps to the padding parameter n ; pinning down $\delta(m,k)$ would convert orbit-closure containment questions into a finite linear-algebraic check. Because Young flattenings are computed by listing semistandard Young tableaux and writing an explicit polynomial-sized matrix of monomial coefficients, the obstruction is constructive and respects the GL_n^2 -symmetry that defeats natural-proofs and algebrization barriers. A clean quantitative law here would directly sharpen Mulmuley-Sohoni's program for separating VP from VNP via Per vs Det.

             ~^^^
```

IndexError: list index out of range

Judge reasoning

The test crashed with an `IndexError` in `gaussian_elimination` before producing any $\delta(m,k,n)$ data, so the pre-registered support condition could not be evaluated. Per Rule 2, a crash yields INCONCLUSIVE. | next: Fix the `gaussian_elimination` routine (handle zero-pivot/short-row cases, e.g., add partial pivoting and bounds checks) and rerun the deterministic sweep over $m \in \{2,3,4\}$, $1 \leq k \leq m-1$, $n \in \{m^2, \dots, m^2+4\}$.

Pebble-Cost Gadget Lifts Decision Tree Depth to KW-Game Length

- **Verdict:** INCONCLUSIVE
- **Bridge:** Black-white pebbling games on rooted DAGs (Cook-Sethi pebbling cost) $\times$ Karchmer-Wigderson communication complexity on lifted query problems
- **Recorded:** 2026-04-27 01:38 UTC
- **Entry ID:** 52cebd2ffe62

Statement

Let f be a partial Boolean function on m bits and let G_f be the canonical AND/OR DAG of its minimum-depth decision tree T_f , with black-white pebbling cost $p(G_f)$. Define the lifted relation $f \circ g$ where g is the 2-bit indexing gadget `IND_2` on $b=2$ address bits, and let $KW(f \circ g)$ denote the deterministic KW-game length on $f \circ g$. Then for every f with $|T_f| \leq 2^m$ and $m \leq 12$, $KW(f \circ g) =$

$\text{depth}(T_f) + p(G_f) \pm 1$, i.e. the lifted KW length equals the tree depth plus the pebbling cost of its DAG up to additive 1.

Rationale

Raz-McKenzie style lifts add a multiplicative gadget overhead, but the *exact* additive correction has never been pinned to a classical DAG invariant; pebbling cost measures exactly the simultaneous-memory needed to simulate the tree as a circuit, which is precisely the resource the KW-prover must spend to track gadget answers. If correct, this gives a tight (not asymptotic) lifting identity computable on tiny instances, sharper than known $O(\text{depth} \cdot \log b)$ bounds. It also explains why IND_2 already suffices for many separations: the gadget cost is absorbed by pebbling rather than by an extra log factor.

UnboundLocalError: cannot access local variable 'm' where it is not associated with a value

Judge reasoning

The test crashed with an UnboundLocalError before producing any data, so the pre-registered support condition (≥ 200 samples with $|k-d-p| \leq 1$ for 100%) was never evaluated. No counterexample was observed either, so neither support nor falsification is established. | next: Fix the variable-scoping bug in run_trial (initialize m before the conditional reassignment) and rerun the full sweep over $m \in \{3, \dots, 12\}$ to obtain the required ≥ 200 samples.

Mealy Automaticity Lower-Bounds Truth-Table Formula Size

- **Verdict:** INCONCLUSIVE
- **Bridge:** Finite-state transducer minimization / 2-automaticity of binary sequences (Allouche-Shallit automaticity over the alphabet $\{0,1\}$, distinct from any compression-based complexity) × Meta-complexity: minimum $\{\text{AND,OR,NOT}\}$ -formula leaf count $L(f)$ of a truth table, used as a tractable MCSP proxy
- **Recorded:** 2026-04-27 02:14 UTC
- **Entry ID:** 33ac9cdf1529

Statement

For an n -variable Boolean function f with truth table $T_f \in \{0,1\}^{2^n}$, let $A(f)$ be the number of states of the minimum complete DFA over alphabet $\{0,1\}$ that accepts $L_f = \{ \text{bin}_n(k) : T_f[k] = 1 \}$, where $\text{bin}_n(k)$ is the n -bit MSB-first binary expansion of k . Let $L(f)$ be the leaf-count of the smallest $\{\text{AND,OR,NOT}\}$ -formula computing f over the literals $x_1, \dots, x_n, \neg x_1, \dots, \neg x_n$. Conjecture:

for every $n \geq 2$ and every f , $A(f) \leq (n+2) \cdot L(f) + 2$; equivalently, $\log_2 A(f) \leq \log_2 L(f) + \log_2(n+2) + o(1)$. A single Boolean function violating this bound refutes the conjecture.

Rationale

Mealy/DFA state count is a transducer-theoretic measure that has been intensively studied for infinite automatic sequences but almost never tied directly to MCSP-style formula minimization on truth tables; small formulas should yield few distinguishable prefix-evaluation states, suggesting at most a linear-in- n blow-up from $L(f)$ to $A(f)$. This bridge converts an MCSP question into a poly-time-computable transducer invariant (Hopcroft minimization), giving a falsifiable surrogate without needing to solve MCSP itself. If the bound fails, the offending function exposes a ‘state-rich, formula-cheap’ object — a new natural property candidate that would not relativize, fitting the META_COMPLEXITY safe-direction profile.

Judge reasoning

The test crashed with a `TypeError` in `truth_table_to_dfa` before any function was evaluated, so no $A(f)$ or $L(f)$ data was produced and the pre-registered support condition cannot be checked. | next: Fix the DFA construction (state representation type bug in `get_next_state`) and rerun the enumeration/sampling protocol over $n \in \{2, \dots, 8\}$.

Tropical Positive-Scalar Homogeneity of MinimalFourierCoefficient

- **Verdict:** INCONCLUSIVE

- **Bridge:** TROPICAL_FOURIER_ANALYSIS (tropical geometry $\times$ Fourier analysis over the max-plus semiring) $\times$ Min-plus circuit complexity / tropical circuit lower bounds (a complexity-theoretic measure governing shortest-path and dynamic-programming circuits)
- **Recorded:** 2026-04-27 02:28 UTC
- **Entry ID:** 6be01f5e483c

Statement

Let f be a TropicalPolynomial on a finite grid $X \subset \mathbb{R}^d$, and let $\lambda > 0$. Define the tropically rescaled polynomial $g = \lambda \odot f$, i.e., the pointwise rescaling $g(x) = \lambda \cdot f(x)$ (tropical exponentiation by λ). Let $F = \text{TropicalFourierTransform}(f)$ and $G = \text{TropicalFourierTransform}(g)$ be their tropical Fourier coefficients (the Legendre–Fenchel-type transforms guaranteed invertible by axiom A2 on the relevant class). Then $\text{MinimalFourierCoefficient}(g) = \lambda \cdot \text{MinimalFourierCoefficient}(f)$, and $\text{DiscrepancyCalculation}(g) = \lambda \cdot \text{DiscrepancyCalculation}(f)$. In particular, the bound from axiom A3, $\text{DiscrepancyMeasure}(h) \leq \max_k |\hat{F}_h(k)|$, scales homogeneously of degree 1 under positive tropical rescaling, so the inequality is preserved exactly under $\lambda > 0$ (no slack opens or closes).

Rationale

This conjecture directly tests axiom A3 ($\text{DiscrepancyMeasure} \leq \max \text{Fourier coefficient}$) jointly with axiom A2 (invertibility of $\text{TropicalFourierTransform}$ on the chosen class). Because tropical multiplication by a positive scalar corresponds to ordinary multiplication, and the Legendre–Fenchel transform satisfies $(\lambda \cdot f)(y) = \lambda \cdot f(y/\lambda)$, both extremes of f^* (its minimum and the discrepancy it controls) must scale by exactly λ . Verifying this 1-homogeneity is a clean sanity check that the framework’s notion of $\text{MinimalFourierCoefficient}$ behaves as a genuine ‘norm-like’ invariant compatible with the tropical semiring’s scalar action, and that the A3 bound is not an artifact of a particular scale (relevant for transferring lower bounds in tropical/min-plus circuit complexity, where rescaling weights is a standard reduction).

NameError: name 'x' is not defined

Judge reasoning

The test crashed with a NameError (‘x’ is not defined’) before any trials executed, so no data was produced to evaluate the pre-registered support or falsification conditions. | next: Fix the test harness by properly defining the grid points x within the polynomial generation (e.g., evaluate the affine forms over each grid point), then rerun the 5000 trials.

Permanent-Variance of NW Design Matrix Predicts PRG Bias

- **Verdict:** INCONCLUSIVE
- **Bridge:** Combinatorics of 0/1 matrix permanents (Ryser-formula variance over random row-sign perturbations) $\times$ Nisan-Wigderson pseudorandom generator output bias against small DNF distinguishers
- **Recorded:** 2026-04-27 02:42 UTC
- **Entry ID:** 92f05cc72075

Statement

Let D be an (ℓ, a) -NW design on n variables encoded as an $m \times n$ 0/1 incidence matrix M (rows = subsets S_i , columns = universe). Define $V(M) := \log_2(1 + \text{Var}_{\{\text{eps} \in \{+/-1\}^n\}}[\text{perm}(M_{\text{eps}})]) / m$, where M_{eps} is M with column j scaled by eps_j and perm is the 0/1 permanent on the $(m \times m)$ submatrix induced by the m heaviest columns. We conjecture that for every hard truth table $f : \{0,1\}^\ell \rightarrow \{0,1\}$ of formula-leaf-count $L(f) \geq 2^{\ell/3}$, the maximum bias of $\text{NW}_{\{D,f\}}$ against width- w DNF distinguishers satisfies $\text{bias}(\text{NW}_{\{D,f\}}, w) \leq 2^{-c * V(M) * m / w}$ for an absolute constant $c > 0$, so $V(M)$ is a constructive lower bound certificate for PRG quality.

Rationale

Permanent variance over sign perturbations measures how ‘spread’ the design’s row-overlap pattern is, which is exactly the combinatorial quantity controlling pairwise-intersection cancellation in the NW hybrid argument; existing analyses use only $|S_i \cap S_j| \leq a$, but the variance aggregates higher-order interference. Linking permanent fluctuation (a 0/1 matrix invariant computable in $O(m * 2^m)$ by Ryser) to NW bias is, to our knowledge, unstudied and sidesteps natural-proofs because the invariant depends on the design only, not on f ’s truth table.

                      ~~~~~^
```

IndexError: list index out of range

Judge reasoning

The test crashed with an `IndexError` before producing any data, so no support fraction or violation ratio could be computed against the pre-registered criterion. | next: Fix the indexing bug in the permanent computation (the `M_heaviest` submatrix access uses `M_heaviest[j][i]` where `j` ranges over `m` but rows are indexed differently) and rerun the trials.

Cycle-Space Cocycle Imbalance Lower-Bounds Resolution Width of Tseitin

- **Verdict:** INCONCLUSIVE
- **Bridge:** Algebraic graph theory: $\text{GF}(2)$ cycle space and edge-boundary cocycle imbalance of expander graphs $\times$ Resolution refutation width of Tseitin formulas on bounded-degree expanders
- **Recorded:** 2026-04-27 03:18 UTC
- **Entry ID:** 09c50eb1a365

Statement

Let $G=(V,E)$ be a connected 3-regular graph and let $T(G,c)$ be the Tseitin formula for an odd charge $c:V \rightarrow \{0,1\}$. Define the cocycle imbalance $I(G) = \min \text{ over nonempty } S \text{ subset } V \text{ of } |E(S, V \setminus S)| / \min(|S|, |V \setminus S|)$, and let $w(T(G,c))$ denote the minimum width of any resolution refutation of $T(G,c)$. The conjecture is the linear lower bound $w(T(G,c)) \geq \text{floor}(I(G) * \min(|S|, |V \setminus S|) / 2) + 1$, where S is the cocycle-imbalance minimizer; equivalently, resolution width is at least half the minimum odd-charge edge-boundary plus one.

Rationale

Ben-Sasson-Wigderson tie resolution width to expansion of the underlying constraint hypergraph, and Urquhart's classical Tseitin lower bounds are driven by edge-boundary expansion of small vertex sets. Reformulating expansion as a $\text{GF}(2)$ cocycle imbalance (the dual of cycle-space sparsity) gives a coordinate-free invariant that should sharpen the constant in width lower bounds, and falsification on a single 3-regular graph would refute a clean algebraic strengthening of the BSW bound.

Empirical Test

- exit code: 124, elapsed: 180.08s

TIMEOUT after 180s

Judge reasoning

The test timed out after 180s (returncode=124) without producing any RESULT line, so the pre-registered support condition over ≥ 210 instances was never evaluated. | next: Re-run with a higher time budget and/or a faster width-bounded resolution solver (e.g., restrict to $n \leq 14$ first, parallelize per-instance, and cache $I(G)$ computations) to actually collect the 210 data points.

Halton Star-Discrepancy of Clause-Sign Embedding Bounds DPLL Leaves

- **Verdict:** INCONCLUSIVE
- **Bridge:** Quasi-Monte Carlo low-discrepancy sequence theory (Halton/van der Corput star-discrepancy) $\times$ DPLL search-tree leaf count on random 3-CNF instances
- **Recorded:** 2026-04-27 03:49 UTC
- **Entry ID:** c4e28e9508f6

Statement

Embed each clause C_i of a 3-CNF F over n variables as a point p_i in $[0,1]^3$ by writing the three signed-literal indices (*signvar*) in *base-2 reversed (van der Corput) coordinates*, then let $D(F)$ be the empirical star-discrepancy of $\{p_i\}$ relative to the uniform measure on $[0,1]^3$. Conjecture: for unsatisfiable random 3-CNF at clause density $\alpha=4.267$, the DPLL leaf count $L(F)$ satisfies $\log_2 L(F) \geq c \cdot n \cdot D(F) - O(\log n)$ with $c = 1/2$, and equivalently $\log_2 L(F) \leq C \cdot n \cdot D(F) + O(\log n)$ with $C = 4$. A single instance with $\log_2 L(F) < 0.4 \cdot n \cdot D(F) - 5$ ($n \leq 20$) falsifies the lower bound.

Rationale

Star-discrepancy measures how ‘evenly’ clause-signatures fill literal-space; Chazelle/Matousek showed star-discrepancy controls combinatorial concentration phenomena that mirror branching irregularity. Highly clustered clause-embeddings (low discrepancy in sub-boxes) should correspond to local refutations exploitable by short DPLL trees, while highly dispersed sets force the splitter to branch globally. The bridge is constructive (just digit-reversal + brute search-tree count) and bypasses natural-proofs since star-discrepancy is not a pseudorandom-friendly invariant.

Novelty

Empirical Test

- exit code: 124, elapsed: 180.03s

TIMEOUT after 180s

Judge reasoning

The test timed out after 180s (returncode=124) without producing any data, so neither the support condition nor the falsification condition could be evaluated. | next: Reduce the workload (e.g., fewer seeds per n or cap n at 16) and/or add per-instance timeouts so the 1200-seed sweep can complete within the budget.

Erdős-Ko-Rado Shadow Defect Lower-Bounds Disjointness Discrepancy

- **Verdict:** INCONCLUSIVE
- **Bridge:** Extremal set theory via Kruskal-Katona shadow profiles and EKR-type intersecting family deficits $\times$ Discrepancy-based randomized two-party communication complexity of partial set-disjointness matrices
- **Recorded:** 2026-04-27 04:23 UTC

- **Entry ID:** 78c33f7389a9

Statement

For an $n \times n \pm 1$ matrix M_F constructed from a k -uniform set family $F \subseteq \{0,1\}^n$ (rows = members of F , columns = members of F , entry = +1 if disjoint, -1 if intersecting), let $s(F)$ be the Kruskal-Katona shadow defect, defined as $|\partial F| - \text{KK_min}(|F|, k-1)$ where ∂F is the $(k-1)$ -shadow and KK_min is the colex minimum, and let $\delta(F)$ be the spectral discrepancy $\|M_F\|_{\infty \rightarrow 1} / (|F|^2)$. We conjecture that for every k -uniform F with $2 \leq k \leq n/2$, $\delta(F) \geq c \cdot s(F) / (|F| \cdot \text{binomial}(n, k-1))$ for a universal constant $c \geq 1/8$, with equality approached only by colex-initial (EKR-extremal) families. A single (n, k, F) with $\delta(F) < (1/8) \cdot s(F) / (|F| \cdot C(n, k-1))$ refutes it.

Rationale

Shadow profiles measure how far a family deviates from being a colex-initial intersecting EKR family, and EKR-extremal stars are exactly the configurations whose disjointness matrices are known to be low-rank/low-discrepancy; quantifying the gap should pin discrepancy to a combinatorial deficit rather than spectral norms. This bridges Kruskal-Katona extremal shadow theory — almost untouched in communication complexity — with the discrepancy method via a constructive, polytime-computable invariant. If true, it would yield discrepancy lower bounds from purely combinatorial shadow counts, sidestepping algebrization since shadows are not relativizing.

Empirical Test

- exit code: 124, elapsed: 180.10s

TIMEOUT after 180s

Judge reasoning

The test timed out at 180s (returncode 124) before producing any data, so neither the support nor falsification condition can be evaluated. The critic's CHALLENGE stands. | next: Reduce the search space (e.g., $n \in \{8..12\}$, $k \in \{2,3\}$, 50 random samples per cell) and optimize the spectral discrepancy computation (use $\|M\|_{\infty \rightarrow 1}$ via sign-vector enumeration only for small $|F|$, or a Grothendieck-style SDP relaxation) to fit within the time budget.

Edge-Expansion Defect Predicts Resolution Width of Tseitin on Random 3-Regular Graphs

- **Verdict:** INCONCLUSIVE
- **Bridge:** Discrete differential geometry via vertex-weighted Cheeger defect: the gap between the bottleneck edge-isoperimetric ratio $h(G)$ and its second-eigenvalue Cheeger upper bound $2\sqrt{d\lambda_2(L)}$ on the unnormalized graph Laplacian $\times$ Resolution refutation width of Tseitin formulas $T(G, c)$ on small 3-regular graphs with odd total charge
- **Recorded:** 2026-04-27 04:57 UTC
- **Entry ID:** c3c56f86d197

Statement

Let G be a connected 3-regular graph on n vertices with odd-charge assignment c , let $h(G) = \min_{|S| \leq n/2} |E(S, V \setminus S)|/|S|$ be its edge-isoperimetric number, and let $\beta(G) = 2\sqrt{3\lambda_2(L_G)}$ be the Alon-Milman/Cheeger upper bound. Define the Cheeger defect $\Delta(G) = \beta(G) - h(G) \geq 0$. We conjecture that the minimum resolution refutation width $w(T(G, c))$ satisfies $(1/3)h(G)(n - \Delta(G)n/\beta(G)) - 2 \leq w(T(G, c)) \leq h(G)n/2 + 2$ for every odd-charge c , and in particular the *defect-corrected* lower bound $h(G)(1 - \Delta(G)/\beta(G))n/3 - 2$ is tight up to constants on random 3-regular graphs with high probability.

Rationale

Ben-Sasson-Wigderson tied resolution width to expansion of the underlying constraint hypergraph, but the standard bound uses $h(G)$ only and is loose when the spectral gap fails to certify expansion globally; the Cheeger defect $\Delta(G)$ quantifies exactly how much the linear-algebraic certificate underestimates the combinatorial bottleneck, which we hypothesize is the slack absorbed by short resolution refutations exploiting near-bisecting cuts. Because both $h(G)$ and $\lambda_2(L_G)$ are computable for $n \leq 20$ by brute-force enumeration over subsets and a 20x20 eigensolver, the bridge is fully constructive. The bridge is genuinely new because existing Tseitin lower bounds use $h(G)$ directly or pseudo-expectation arguments and do not isolate the spectral-vs-isoperimetric gap as a width predictor.

Novelty

```

TypeError: unsupported operand type(s) for /=: 'list' and 'float'

Judge reasoning

The test crashed with a `TypeError` in `power_iteration` (dividing a Python list by a float) before any instances were evaluated, so neither the support nor falsification criteria could be assessed. | next: Fix `power_iteration` to use a numpy array (or convert `x` to an array before normalization) and rerun the 210-instance sweep.

Average-Case DPLL Runtime Linked to Random Matrix Spectra

- **Verdict:** INCONCLUSIVE
- **Bridge:** Random Matrix Theory $\times$ DPLL Algorithm Runtime
- **Recorded:** 2026-04-27 06:23 UTC
- **Entry ID:** 7ac5fad5a356

Statement

For random 3-CNF formulas with n variables, the expected DPLL runtime is exponentially bounded by the largest eigenvalue $\lambda_{\max}$ of the clause adjacency matrix, i.e., $E[T(n)] = \Theta(2^{\lambda_{\max} * n})$.

Rationale

Random matrix theory provides tools to analyze the spectral properties of structured matrices derived from CNF formulas. By linking the runtime of DPLL to the spectral radius of such matrices, we can derive worst-case hardness from average-case behavior, leveraging the concentration of measure phenomena in random matrices.

Betti Numbers and Resolution Width in 3-CNF

- **Verdict:** INCONCLUSIVE
- **Bridge:** Algebraic Topology $\times$ Resolution Width
- **Recorded:** 2026-04-27 07:04 UTC
- **Entry ID:** 6bc88662420d

Statement

For a random 3-CNF instance with n variables, the first Betti number of the clause-induced simplicial complex is $\Theta(\log n)$ if and only if the resolution width is $\Theta(\log n)$.

Rationale

Algebraic topology provides tools to analyze the structure of clause interactions, which may reveal hidden geometric constraints influencing resolution proof complexity. Betti numbers capture topological features that could correlate with the width required for resolution proofs.

Novelty

    raise TypeError("Population must be a sequence. ")
TypeError: Population must be a sequence. For dicts or sets, use sorted(d).
```

Judge reasoning

The test crashed with a `TypeError` (`random.sample` called on a non-sequence) before any Betti numbers, resolution widths, or correlations were computed, so the pre-registered support condition cannot be evaluated. | next: Fix the bug by passing a sorted list (e.g., `random.sample(sorted(variable_set), 3)`) and rerun the 140-instance sweep to obtain b_1 , w , and their correlation.

Sandpile-Group Order of Lifted IP Bipartite Graph Bounds Decision Tree Depth

- **Verdict:** INCONCLUSIVE
- **Bridge:** Algebraic graph theory via the critical (sandpile) group $K(G)$ and Kirchhoff's Matrix-Tree theorem applied to bipartite communication graphs (rare in CS lower bounds; cf. Bacher-de la Harpe-Nagnibeda, Biggs) $\times$ Deterministic communication complexity of Raz-McKenzie / Göös-Pitassi-style lifted Boolean functions $f \circ \text{IP}_b^n$ with the inner-product gadget
- **Recorded:** 2026-04-27 07:15 UTC
- **Entry ID:** 69ad4d50946e

Statement

Let $f: \{0,1\}^n \rightarrow \{0,1\}$ have exact decision-tree depth $d=D(f)$, let $b \in \{2,3\}$ be the IP-gadget block size, and let $M(f,b) \in \{0,1\}^{2\{bn\} \times 2^{bn}}$ be the lifted communication matrix with $M[x,y] = f((x_1, y_1), \dots, (x_n, y_n))$ over $GF(2)$. Form the bipartite graph $G(f,b)$ with rows on one side, columns on the other, and an edge exactly where $M[x,y]=1$; let $\tau(G)$ denote its spanning-tree count (Kirchhoff determinant of any reduced Laplacian, with $\tau=0$ if disconnected and τ a product over components otherwise). Conjecture: for every non-constant f with $n \leq 3$ and $b \in \{2,3\}$, $\log_2 \tau(G(f,b)) \geq d \cdot 2^{bn-2}$, and equality is achieved (within $+b$) precisely when f is the parity (XOR _{n}) function.

Rationale

Lifting overhead per block in deterministic IP-lifting morally measures how many distinct rectangles each query forces; the sandpile group order is the lattice index of the cycle/cut spaces of G and counts admissible flow/charge configurations on G 's bipartite structure. Linking $\tau(G)$ to $D(f) \cdot (\text{gadget block area})$ plants a query-to-communication bridge through pure graph algebra, sidestepping algebraization since spanning-tree counting is not a relativizing arithmetic primitive. Tightness on parity is suggested because XOR-lifted matrices are Hadamard-like, giving maximally regular Laplacian spectra and hence nearly extremal spanning-tree counts.

Novelty

     ^^^^^^^^^
```

NameError: name 'lru_cache' is not defined

Judge reasoning

The test crashed with a NameError ('lru_cache' is not defined) before producing any data, so no support fraction or slack values were computed. Per the rules, a crashed test yields INCONCLUSIVE. | next: Fix the test by importing lru_cache from functools (add 'from functools import lru_cache') and rerun the full enumeration over $n \in \{1,2,3\}$, $b \in \{2,3\}$.

Doob Martingale Variance Gap Predicts Worst-Case DPLL Depth

- **Verdict:** INCONCLUSIVE
- **Bridge:** Doob martingale concentration / Efron-Stein variance decomposition on random CSP exposures $\times$ DPLL search-tree depth on random 3-CNF (average-case to worst-case lift)
- **Recorded:** 2026-04-27 07:44 UTC
- **Entry ID:** 6487f7d68c31

Statement

Let $F \sim F(n, m=4n)$ be a random 3-CNF and let $X(F) = \log_2(\text{DPLL_leaves}(F))$ under fixed unit-propagation + first-unassigned variable order. Expose clauses one at a time to form the Doob martingale $M_i = E[X \mid C_1, \dots, C_i]$ and let $V(F) = \sum_i (M_i - M_{i-1})^2$ be its realized quadratic variation. Then for every n in $[10, 20]$ there exist constants $c_1, c_2 > 0$ (independent of n) with $c_1 * \sqrt{V(F)} * \log n \leq \max_{\{F' \text{ agreeing with } F \text{ on all but one clause}\}} X(F') - E[X] \leq c_2 * \sqrt{V(F)} * \log n$ with probability $\geq 1 - 1/n$; equivalently, the average-case Doob variance $V(F)$ tightly predicts the one-clause-perturbation worst-case depth gap.

Rationale

Efron-Stein variance bounds give average-case concentration, but the lower-tail (one-clause-resampling worst-case) is rarely tied to the same martingale variance — yet Impagliazzo-Wigderson-style hardness amplification suggests average-case fluctuation should control nearby worst-case spikes. If the two-sided bound holds, an average-case lower bound on V translates into a worst-case DPLL depth bound via a single resampling step, a concrete avg-to-worst lift on a small computable scale.

Novelty

- Judge: NOVEL over 9 arXiv hits

RESULT: SUPPORTED mean=0.0 std=0.0 support_fraction=1.0
```

Judge reasoning

The metric_value is exactly 0 with zero variance across all 5 seeds and only 6 instances per seed, indicating the test likely checked a trivially-satisfiable existential bound rather than the pre-registered OLS $R^2/\text{slope}/\text{window-fraction}$ criterion. No evidence of pooled R^2 , fitted slope, or per- n window fractions was reported, so the support condition is not unambiguously met. | next: Re-run with seeds 1..200 across n in $\{10, 12, 14, 16, 18, 20\}$ and explicitly compute pooled OLS regression of $\log(\text{gap})$

Newton-Inequality Defect of SAT Generating Polynomial Bounds DPLL Depth

- **Verdict:** INCONCLUSIVE
- **Bridge:** Pólya-Schur theory of real-rooted polynomials and Newton's inequalities (multiplier sequences, log-concavity defects of integer coefficient polynomials) × Average-case DPLL search-tree depth on random 3-CNF and its direct-product worst-case lift
- **Recorded:** 2026-04-27 08:18 UTC
- **Entry ID:** 4907d4d1fa3e

Statement

For a 3-CNF F on n variables, define the solution generating polynomial $\Phi_F(z) = \sum_{k=0}^n a_k(F) z^k$ where $a_k(F) = \#\{x \in \{0,1\}^n : F(x)=1 \text{ and } \text{weight}(x)=k\}$, and let the Newton-inequality defect be $\delta(F) = \max_{1 \leq k \leq n-1} \max(0, a_{k-1} a_{k+1} / a_k^2 - (k-1)(n-k+1)/(k(n-k+1)))$ with the convention $0/0 = 0$. Conjecture: there exist constants $c_1, c_2 > 0$ (independent of n) such that for random satisfiable 3-CNF F at clause density α in $[3.6, 4.0]$, the expected average-case DPLL leaf count satisfies $E[\log_2 \text{leaves_DPLL}(F)] \geq c_1 * n * \log_2(1 + \delta(F)) - c_2 * \sqrt{n}$, and the k -fold disjoint-variable direct product $F^{\{(k)\}}$ satisfies $\text{leaves_DPLL}(F^{\{(k)\}}) \geq (1 + \delta(F))^{\{c_1 * k * n\}}$ for every static branching order. The conjecture is falsified by exhibiting a single F (with $n \leq 20$) whose measured leaf count is below $c_1 * n * \log_2(1 + \delta(F)) - c_2 * \sqrt{n}$ for $c_1 = 0.25, c_2 = 4$.

Rationale

Pólya-Schur theory says that polynomials with only real (negative) roots satisfy Newton's inequalities exactly; the defect δ quantifies how far Φ_F is from being a multiplier-stable polynomial. Real-rooted Φ_F corresponds to clusters of solutions arranged like an independent-coordinate product distribution, which DPLL prunes efficiently; conversely, large δ signals pinned correlations between Hamming-weight strata of the solution set, which force DPLL backtracks. Direct product then transports this average-case structural obstruction to a worst-case depth lower bound in the spirit of Impagliazzo-Wigderson hardness amplification.

Let $f: \{0,1\}^n \rightarrow \{0,1\}$ be monotone with prime-implicant supports $S_1, \dots, S_k \subseteq [n]$; let L_f be the meet-closure lattice generated by $\{S_i\}$ together with an adjoined top $\hat{1} = [n]$ and bottom $0 = \emptyset$, and let $\mu_f = |\mu_{\{L_f\}}(0, \hat{1})|$ be its Möbius number. Then for all $n \leq 20$ the deterministic decision-tree depth satisfies $D^{dt}(f) \geq \lceil \log_2(1 + \mu_f) \rceil$, and consequently the Göös-Pitassi-Watson Indexing-gadget lifting yields $D^{cc}(f \circ \text{IND}_b) = \Omega((\log b) \cdot \log_2(1 + \mu_f))$. A single monotone f with $\lceil \log_2(1 + \mu_f) \rceil > D^{dt}(f)$ refutes the conjecture.

Lifting theorems convert decision-tree depth to communication, so any combinatorial invariant that lower-bounds $D^{\text{dt}}(f)$ automatically lower-bounds lifted communication. The Möbius number of the minterm closure lattice measures how much non-Boolean-lattice structure the accepting set carries; intuitively, each query in a decision tree can only halve the alternating Möbius sum on a chain, so depth must dominate $\log$ of $|\mu|$. This bridges topological combinatorics to communication lower bounds, a pairing with no prior occurrences I am aware of.

NameError: name 'a' is not defined

Judge reasoning

The test crashed with a NameError in generate_random_dnf (undefined variable 'a' in a generator expression) before any instances were evaluated, so no data was produced for either the support or falsification criterion. | next: Fix the generator-expression bug in generate_random_dnf (likely should iterate over candidate 'a' against existing implicants 'b') and rerun the 400-instance sweep.

Noise-Stability Plateau at $\rho=1/3$ Bounds DPLL Leaves on 3-CNF

- **Verdict:** INCONCLUSIVE
- **Bridge:** Fourier analysis of Boolean functions (noise stability Stab_ρ and Bonami-Beckner noise operator T_ρ) $\times$ DPLL search-tree leaf count on random 3-CNF formulas
- **Recorded:** 2026-04-27 09:18 UTC
- **Entry ID:** 3385dd792f63

Statement

For a 3-CNF formula F on n variables with indicator function $f_F: \{-1, 1\}^n \rightarrow \{0, 1\}$ (1 iff assignment satisfies F), let $S(F) := \text{Stab}_{1/3}(f_F) - (E[f_F])^2 = \sum_{|T| \geq 1} (1/3)^{|T|} \hat{f}_T^2$. We conjecture that for every unsatisfiable 3-CNF F with m clauses on $n \leq 20$ variables, the number $L(F)$ of leaves explored by the standard unit-propagating DPLL with fixed lexicographic branching satisfies $L(F) \geq 2^n \cdot S(F) / (3 \cdot m)$, and equivalently for satisfiable F we get $L(F) \leq 2^n \cdot (1 - 9 \cdot S(F)/m)$. One satisfiability instance violating either inequality refutes the conjecture.

Rationale

At noise rate $1/3$ each clause's local indicator (a degree-3 Boolean function on three variables) decays by exactly $(1/3)^3 = 1/27$ per level, matching the branching factor of DPLL on a 3-CNF; thus

the $\rho=1/3$ noise stability isolates the 'clause-coupled' Fourier mass that DPLL must shatter. Kahn-Kalai-Linial-style influence bounds show that each clause contributes at most $O(1/n)$ to total influence, so summing $\text{Stab}_{\{1/3\}}$ over clauses should track tree size up to the clause-density factor m . This bridges hypercontractive Fourier weight with concrete branching cost, a connection rarely tested empirically.

UnboundLocalError: cannot access local variable 'f_F' where it is not associated with a value

Judge reasoning

The test crashed with an UnboundLocalError before producing any data, so no instances were evaluated and neither the support nor falsification condition can be assessed. | next: Fix the test harness bug (initialize `f_F` properly before constructing the assignment-to-evaluation dictionary) and rerun the full 1050-instance sweep.
